We carry out a high-precision Monte Carlo simulation of the two-dimensional $O(3)$ -invariant σ -model at correlation lengths ξ up to $\sim 10^5$. Our work employs a new and powerful method for extrapolating finite-volume Monte Carlo data to infinite volume, based on finite-size-scaling theory. We compare the extrapolated data to the renormalization-group predictions. The deviation from asymptotic scaling, which is $\approx 25\%$ at $\xi \sim 10^2$, decreases to $\approx 4\%$ at $\xi \sim 10^5$.

We study the lattice σ -model taking values in the unit sphere $S^{N-1} \subset \mathbb{R}^N$, with nearest-neighbor action $\mathcal{H}(\boldsymbol{\sigma}) = -\beta \sum \boldsymbol{\sigma}_x \cdot \boldsymbol{\sigma}_y$. Perturbative renormalization-group computations through three loops [1,2] predict that the exponential correlation length (inverse mass gap) $\xi^{(exp)}$, the second-moment correlation length $\xi^{(2)}$, and the susceptibility χ behave for $N = 3$ (in infinite volume) as

$$\xi^\#(\beta) = C_{\xi^\#} \frac{e^{2\pi\beta}}{2\pi\beta} \left[1 - \frac{0.091}{\beta} + \dots \right] \quad (1)$$

$$\chi(\beta) = C_\chi \frac{e^{4\pi\beta}}{(2\pi\beta)^4} \left[1 - \frac{0.001}{\beta} + \dots \right] \quad (2)$$

as $\beta \rightarrow \infty$. The nonperturbative constant $C_{\xi^{(exp)}}$ has been computed recently using the thermodynamic Bethe Ansatz [3]:

$$C_{\xi^{(exp)}} = 2^{-5/2} \left(\frac{e^{1-\pi/2}}{8} \right). \quad (3)$$

The remaining nonperturbative constants are known analytically only at large N [4]:

$$C_{\xi^{(2)}}/C_{\xi^{(exp)}} = 1 - \frac{0.003225}{N} + O(1/N^2) \quad (4)$$

$$C_\chi = \frac{\pi}{16} \left[1 - \frac{4.267}{N} + O(1/N^2) \right] \quad (5)$$

*Speaker at the conference.

A high-precision Monte Carlo study [5] yields $C_{\xi^{(2)}}/C_{\xi^{(exp)}} = 0.9993 \pm 0.0006$ for $N = 3$, in good agreement with (4). Previous studies up to $\xi \sim 100$ agree with these predictions to within about 20–25% [6].

In order to extrapolate finite-volume Monte Carlo data to infinite volume, we used a novel method [7] based on the finite-size-scaling Ansatz

$$\frac{\mathcal{O}(\beta, sL)}{\mathcal{O}(\beta, L)} = F_{\mathcal{O}}\left(\xi(\beta, L)/L; s\right), \quad (6)$$

which is correct up to terms of order $\xi^{-\omega}$ and $L^{-\omega}$; here $\mathcal{O}$ is any long-distance observable, s is a fixed scale factor (usually $s = 2$), L is the linear lattice size, $F_{\mathcal{O}}$ is a universal function, and ω is a correction-to-scaling exponent. For similar extrapolation methods, see [8,9].

Details of our simulation and of the extrapolation process can be found in Sokal's talk at this conference and in [10]. Our preferred fit is shown in Figure 1, where we compare also with the perturbative prediction

$$F_\xi(x; s) = s \left[1 - \frac{\log s}{8\pi x^2} - \left(\frac{\log^2 s}{128\pi^2} + \frac{\log s}{16\pi^2} \right) \frac{1}{x^4} \right] \quad (7)$$

valid for $x \gg 1$.

Figure 1. $\xi(\beta, 2L)/\xi(\beta, L)$ versus $\xi(\beta, L)/L$. Different symbols indicate different lattice sizes L . Dashed curve is the perturbative prediction (7).

The extrapolated values $\xi_{\infty}^{(2)}$ from different lattice sizes at the same β are consistent within statistical errors: only one of the 24 β values has a χ^2 too large at the 5% level; and summing all β values we have $\chi^2 = 86.56$ (106 DF, level = 92%).

In Figure 2 (points + and ×) we plot $\xi_{\infty, estimate}^{(2)}$ divided by the two-loop and three-loop predictions (1)–(4). The discrepancy from three-loop asymptotic scaling, which is $\approx 16\%$ at $\beta = 2.0$ ($\xi \approx 200$), decreases to $\approx 4\%$ at $\beta = 3.0$ ($\xi \approx 10^5$). This is roughly consistent with the expected $1/\beta^2$ corrections. Notice that the points in the curve fluctuate less than what one would expect on the basis of the reported error bars; this is due to a strong statistical correlation of the estimates for the points with higher values of β . Probably also the slight bump at $2.3 \lesssim \beta \lesssim 2.6$ is spurious, arising from correlated statistical or systematic errors.

We can also try an “improved expansion parameter” [11,2,13] based on the energy $E = \langle \sigma_0 \cdot \sigma_1 \rangle$. First we invert the perturbative expansion [12,2]

$$E(\beta) = 1 - \frac{1}{2\beta} - \frac{1}{16\beta^2} - \frac{0.038512}{\beta^3} + O(1/\beta^4) \quad (8)$$

Figure 2. $\xi_{\infty, estimate}^{(2)} / \xi_{\infty, theor}^{(2)}$ versus β . Error bars are one standard deviation (statistical error only). There are four versions of $\xi_{\infty, theor}^{(2)}$: standard perturbation theory in $1/\beta$ gives points + (2-loop) and × (3-loop); “improved” perturbation theory in $1 - E$ gives points □ (2-loop) and ◇ (3-loop).

and substitute into (1); this gives a prediction for ξ as a function of $1 - E$. For E we use the value measured on the largest lattice; the statistical errors and finite-size corrections on E are less than 5×10^{-5} , and therefore induce a negligible error (less than 0.5%) on the predicted ξ . The corresponding observed/predicted ratios are also shown in Figure 2 (points □ and ◇). The “improved” 3-loop prediction is in excellent agreement with the data.

In Figure 3 we report the ratio

$$R_{\chi}(\beta) = \frac{C_{\chi}}{C_{\xi}^{(2)}} \frac{\chi_{\infty, estimate} / (\xi_{\infty, estimate}^{(2)})^2}{\chi_{\infty, theor} / (\xi_{\infty, theor}^{(2)})^2}, \quad (9)$$

where by the suffix *theor* we denote the one-, two- or three-loop prediction either for the standard perturbation theory in $1/\beta$ or for the “improved” one in $1 - E$. The curves appear to become flat for increasing β and to converge to the same value ≈ 10.8 , thus providing an estimate for the universal ratio $C_{\chi}/C_{\xi}^{(2)}$.

Figure 3. R_χ versus β . There are six versions of perturbation theory: the standard one in $1/\beta$ gives points + (1-loop), $\times$ (2-loop) and $\oplus$ (3-loop); “improved” perturbation theory in $1 - E$ gives points $\square$ (1-loop), $\diamond$ (2-loop) and $\triangle$ (3-loop). Error bars are one standard deviation and are reported only for one series of prediction because they are always the same at fixed β .

Let us summarize the conceptual basis of our analysis. The main assumption is that if the Ansatz (6) with a given function F_ξ is well satisfied by our data for $L_{min} \leq L \leq 256$ and $1.65 \leq \beta \leq 3$, then it will continue to be well satisfied for $L > 256$ and for $\beta > 3$. Obviously this assumption could fail, e.g. if [14] at some large correlation length ($\gtrsim 10^3$) the model crosses over to a new universality class associated with a finite- β critical point. In this respect our work is subject to the same caveats as any other Monte Carlo work on a finite lattice. However, it should be emphasized that our approach does *not* assume asymptotic scaling [eq. (1)], as β plays no role in our extrapolation method. Thus, we can make an unbiased *test* of asymptotic scaling. The fact that we confirm (1) *with the correct nonperturbative constant* (3)/(4) is, we believe, good evidence in favor of the asymptotic-freedom picture.

We wish to thank Jae-Kwon Kim for sharing his data with us, and for challenging us to

push to ever larger values of ξ/L . We also thank Steffen Meyer, Adrian Patrascioiu, Erhard Seiler and Ulli Wolff for helpful discussions. The authors’ research was supported by CNR, INFN, DOE contracts DE-FG05-85ER250000 and DE-FG05-92ER40742, NSF grant DMS-9200719, and NATO CRG 910251.
